

ICOHP Descriptors and Thermodynamic Stability Across a 394-Structure Dataset

Campaign 2: Dataset Construction, VASP+LOBSTER Computation, and Statistical Analysis

Report generated as part of the `viability` project

August 16, 2026

The project’s central question is viability discrimination based on $\Delta(\text{ICOHP})$ (§6.4), across a 394-structure dataset.

1 Objective and Problem Statement

Central research question (see §6.4): does $\Delta(\text{ICOHP})$ — the reaction-ICOHP descriptor for a compound’s decomposition into elements, and specifically the sign-based endobondic/exobondic classification it supports — distinguish thermodynamically stable, metastable, and unstable compounds?

2 Methodology

2.1 Dataset Selection

Materials Project query: unary and binary chemical systems, non-magnetic ($|\text{total magnetization}| \leq 0.01 \mu_B/\text{formula unit}$ — MP’s categorical `magnetic_ordering` field is "Unknown" for $\sim 98\%$ of entries and would have excluded nearly every genuinely non-magnetic compound), no f-block elements. The dataset combines two complementary selection tracks: a first set of 186 compounds (≤ 20 atoms/cell, 60 per stability family, a 2-entries-per-chemical-system cap to ensure elemental diversity rather than many polymorphs of the same system), and a second set of 163 compounds/elements (≤ 40 atoms/cell) specifically targeting additional elemental references, off-equilibrium polymorphs (high-pressure phases, allotropes), and alkali/alkaline-earth binaries against N/O/F/P/S/Cl, chosen to build genuine same-composition polymorph groups and to test descriptors far from equilibrium; and a third set of 45 binary compounds, each pairing an experimentally known, maximally metastable compound (farthest above the convex hull among its chemical system) with 1–3 theoretical polymorphs of the same formula sitting even farther above the hull, a robustness test deliberately targeting stability edge cases.

2.2 Bonding-Type Classification

Bond type (ionic / covalent / metallic) is computed by default by the `classify()` function (elemental composition + `is_metal`). A second, independent classification is built directly from each compound’s ICOHP/ICOB data (§5): `is_metal` for metallic character, then the mean ICOBI per bond (bond order, covalency) to separate ionic from covalent among non-metallic compounds. The two classifications are compared in §5.

2.3 VASP + LOBSTER Computation

Same template across all structures (static run, `ISYM=-1`, `LASPH=.TRUE.`, PAW-PBE potentials recommended by `pymatgen.io.vasp.sets.MPrelaxSet`): NBANDS is derived per compound from the number of local orbitals in the LOBSTER basis (`Lobsterin.write_INCAR`), and basis-function determination goes through `Lobsterin.get_basis(potcar_symbols=...)` rather than direct POTCAR-file parsing (whose internal pymatgen validity check fails on several POTCARs unrecognized by hash in the local mirror).

2.4 ICOHP/ICOB Quantities: Integration, Cutoffs, Units

LOBSTER generation (`lobsterin`, identical across the dataset): pbeVasFit2015 basis; COHP integration window from -35 to $+5$ eV around the Fermi level (`COHPstartEnergy/COHPendEnergy`); bond detection by interatomic distance from 0.1 to 6.0 Å (`cohpgenerator`, orbital-resolved); 0.05 eV Gaussian smearing (`gaussianSmearingWidth`).

Integrated ICOHP/ICOB (`ICOHPLIST.lobster/ICOBILIST.lobster`). A bond’s integrated ICOHP is, by LOBSTER’s own definition, the integral of $\text{COHP}(E)$ from the bottom of the window above up to the Fermi level (occupied states only), in eV; negative = bonding, positive = antibonding. ICOBI is the same integral over COBI (bond order index), dimensionless.

These are the per-bond, then per-compound-aggregated, quantities feeding §5 and the classic correlations of §6.

Reaction $\Delta(\text{ICOHP})$ (`reaction_analysis/`). For a balanced reaction (typically compound $\rightarrow$ elements), Δ = sum of products' ICOHP – sum of reactants' ICOHP, "products – reactants" convention, in three normalizations: per formula unit (extensive), per transferred atom (the normalization used throughout this report unless noted), and per bond (diagnostic only, non-conservative — bonds are not conserved between differently-bonded structures). Positive sign ("endobondic"): breaking the reactant's bonds costs more than the products' bonds recover — a possible kinetic barrier. Negative sign ("exobondic"): no such barrier is visible from bonding alone.

Antibonding population near the Fermi level (`cohpp_extraction.py`) — a quantity distinct from the $\Delta(\text{ICOHP})$ above. Rather than integrating the whole occupied COHP, this quantity integrates only its antibonding part ($\text{COHP} > 0$) over a one-sided window ($E_{\text{ref}} - \Delta E, E_{\text{ref}}$], where $E_{\text{ref}} = E_F$ (metallic compounds) or the VBM (gapped compounds), and $\Delta E \in \{0.5, 1.0, 2.0\}$ eV ($\Delta E = 1.0$ eV as the primary window) — only occupied states can destabilize the ground state via antibonding, hence the one-sided rather than symmetric window. Reported both raw (same "eV" unit convention as LOBSTER, though it is a Hamilton population integral, not literally an energy) and normalized by the total occupied ICOHP magnitude at the same E_{ref} . This quantity, and only this one, feeds the descriptor in §6.2 — the reaction $\Delta(\text{ICOHP})$ (§6.3–6.4) integrates the whole occupied COHP with no restriction to a window near E_F .

2.5 Statistics

Spearman correlation (no reason to expect a linear relationship) between each ICOHP/ICOBI descriptor and a stability target (`energy_above_hull` or `formation_energy_per_atom` depending on the descriptor), overall and per subgroup (`bond_type`, `is_metal`); any $n < 15$ subgroup is explicitly flagged, never presented bare. **No SISSO, no symbolic regression** at this stage (see §9).

3 Workflow Diagram

4 Environment

Identical across all 394 structures (Yargla, VASP 6.5.0, LOBSTER 5.1.1, Python 3.11 `.venv`), extended with: `mp-api`, `pandas`, `scipy`, `scikit-learn`, `matplotlib`, `pydantic`, `pyyaml` (see `requirements.txt`). Per-step core allocation: §8.

5 Dataset

The full set of computed compounds and elements totals **394 structures**.

Table 1: Dataset composition by element count.

Composition	<i>n</i>
Single-element references	68
Multi-element compounds	326
Total	394

Bond type. Two independent classifications (§2.2): the `classify()` function (elemental composition + `is_metal`) and a classification built directly from each compound’s ICOHP/ICOBI data (`is_metal` for metallic character, then a threshold on mean ICOBI per bond — calibrated at the midpoint of the median ICOBI of compounds `classify()` already labels ionic/covalent, i.e. 0.0370 — to separate ionic from covalent among non-metallic compounds).

Table 2: Stability class (by E_{hull} and experimental/theoretical character).

Class	n	E_{hull} range (eV/atom)
stable ($E_{\text{hull}} = 0$)	124	0.0000
experimental metastable	137	0.0000347 – 2.1080
theoretical metastable	131	0.0000843 – 3.1688
unknown (COD reference, no E_{hull})	2	—
Total	394	

Table 3: Bond type: `classify()` vs. the ICOHP/ICOB I classification (concordance on the subset `classify()` labels: 159/181 = 87.8%).

<code>classify()</code> \ ICOHP/ICOB I	metallic	ionic	covalent	unclassified
metallic	88	0	0	0
ionic	0	48	5	0
covalent	0	17	23	0
unclassified	138	33	39	1
Total	226	98	67	1

Of the 211 compounds `classify()` leaves "unclassified" (essentially alkali/alkaline-earth $\times$ {N, P, S} pairs outside `IONIC_ANIONS`, and metals bonded to an anion-like element that `classify()` deliberately excludes from its "metallic" bucket), the ICOHP/ICOB I classification resolves **72** into ionic (33) or covalent (39); the remaining 139 are either metallic (138, already covered by `is_metal`) or lack ICOB I data (1). Where both methods render a verdict, agreement is strong (87.8%) but not total: 22 ionic/covalent disagreements, worth checking case by case before using either classification as a stratification variable.

6 Results

6.1 Correlations (Spearman) — classic ICOHP aggregates

Table 4: Spearman correlations, classic ICOHP aggregates (sum, minimum) against E_{hull} , 186-compound subset.

Group	Metric	n	ρ	p
all	ICOHP sum	186	0.032	0.670
all	ICOHP min	186	0.093	0.209
metallic	ICOHP sum	88	0.223	0.037
metallic	ICOHP min	88	0.198	0.065

These four rows serve as a reference baseline: raw ICOHP aggregates (per-compound sum, minimum) show little to no correlation with E_{hull} , except within the metallic subgroup. The descriptors built further on (antibonding population, reaction ICOHP, §6.2–§6.4) do markedly better, against `formation_energy_per_atom` rather than `energy_above_hull`.

6.2 Antibonding Population Near the Fermi Level

A question distinct from the fully-integrated ICOHP (§2.4): not *how much* bonding a compound has, but *how* its COHP is distributed in energy — the occupied antibonding fraction just

below the Fermi level/VBM, by analogy with Peierls/Jahn–Teller-type electronic instabilities. Result, against `formation_energy_per_atom`: $\rho = -0.282$, $p = 9.2 \times 10^{-8}$ ($n = 346$). The sign is the *opposite* of the naive Peierls/Jahn–Teller reading. The `bond_type=covalent` subgroup ($n = 33$) survives stratification clearly ($\rho = -0.551$, $p = 0.0009$) — the project’s most robust stratified result; `is_metal=False` also survives ($n = 157$, $p = 0.001$). An earlier result on the `bond_type=ionic` subgroup ($n = 9$, $\rho = -0.683$) does not replicate once the sample grows to $n = 53$ ($\rho = -0.184$, not significant) — a clear demonstration of the danger of $n < 15$ subgroups.

6.3 Reaction ICOHP

An ICOHP analog of `formation_energy_per_atom`: is a compound’s total ICOHP "cheaper" than that of the same atoms as reference elements? Result: $\rho = 0.502$, $p = 6.3 \times 10^{-19}$ ($n = 275$) — the dataset’s strongest and most robust continuous correlation, with an intuitive sign (less bonding than in elemental form $\Rightarrow$ less stable formation). `bond_type` stratification fully explains this layer of the pooled signal (Kruskal–Wallis $p = 1.1 \times 10^{-15}$, no stratum survives) — **but** `is_metal` stratification survives on both sides (`is_metal=False`: $\rho = 0.319$, $p = 0.0001$; `is_metal=True`: $\rho = 0.256$, $p = 0.0025$): between-group clustering fully explains the `bond_type`-level grouping, but not a real relationship within a fixed `is_metal`. Case 2 (direct same-formula polymorph comparison, 49 groups): 53.1% agreement between the most-bonded and the most-stable member, against a 45.9% chance baseline (exact Poisson-binomial test, $P = 0.19$) — no signal.

Still no SISSO. Reaction ICOHP is the dataset’s strongest raw correlate of `formation_energy_per_atom`, and the only descriptor whose signal is not fully explained away by between-group clustering at every level tested — the best argument yet for a stratified (`is_metal`-conditioned) rather than pooled feature search, still not attempted. Detailed reports: `analysis/REPORT_antibonding.md`, `analysis/REPORT_reaction_icohp.md`.

6.4 $\Delta(\text{ICOHP})$ -Based Viability Discrimination

Full detail: `analysis/REPORT_delta_icohp_viability.md`, `analysis/test_delta_icohp_viability.py`.

Reference validation. Per-bond-type ICOHP values for 7 reactions with independently known ΔICOHP (transcribed independently of any calculation in this project) are run end to end through `balance.py/delta.py/classify.py`:

Table 5: Validating the endobondic/exobondic classification on 7 reactions with independently known ΔICOHP .

Reaction	Reference (kJ/mol)	Computed (kJ/mol)	Label	
			Ref.	Computed
$\text{Pb}(\text{N}_3)_2 \rightarrow \text{Pb} + 3 \text{N}_2$	+1345	+1344.3	endo	endo
$\text{S}_4\text{N}_2 \rightarrow \frac{1}{2}\text{S}_8 + \text{N}_2$	+258	+258.5	endo	endo
$\text{S}_4\text{N}_4 \rightarrow \frac{1}{2}\text{S}_8 + 2\text{N}_2$	+399	+397.3	endo	endo
$\text{ZnSn} \rightarrow \text{Zn} + \text{Sn}$	−337	−336.6	exo	exo
$\text{CaO}[\text{sphalerite}] \rightarrow \text{CaO}[\text{rocksalt}]$	−79	−78.9	exo	exo
$\text{CaN} \rightarrow \frac{1}{3}\text{Ca}_3\text{N}_2 + \frac{1}{6}\text{N}_2$	−205	−204.8	exo	exo
$\text{Mn}_2\text{O}_7 \rightarrow 2\text{MnO}_2 + \frac{3}{2}\text{O}_2$	−186	−187.7	exo	exo

The 7 cases reproduce the reference ΔICOHP to within a few kJ/mol (source per-bond value rounding) and every `BondingLabel` matches. The Mn_2O_7 case is a useful guardrail on its own: exobondic under this static sign criterion, yet Mn_2O_7 is a real, observed compound that simply decomposes slowly (gradual O_2 loss) rather than through abrupt bond breaking — `classify.py` structurally attaches a warning to *every* `UNSTABLE_NONEXISTENT` verdict for exactly this reason, rather than special-casing Mn_2O_7 .

Correlation alone (Pearson/Spearman) is not the right test for "do our numbers match the reference values" — it is satisfied by any monotonic relationship, even with a large systematic offset or scale factor. **Lin’s concordance correlation coefficient** (CCC) specifically tests agreement with the identity line (computed = reference), the claim actually being tested here:

Table 6: Computed-vs-reference concordance on the 7 validation reactions.

Statistic	Value
n	7
Lin’s CCC	0.999998
Pearson r	0.999999 ($p = 3.5 \times 10^{-15}$)
Sign agreement	7/7
Mean residual	0.76 kJ/mol
Max residual	1.70 kJ/mol
RMSE	0.98 kJ/mol

A CCC this close to 1 means the two methods agree essentially to the reporting precision of the reference values themselves (rounded to 2–3 decimals), not merely that they move together — the implementation is validated, not just spot-checked.

Applied to the full dataset, pooled. 281 case-1 reactions, every element and compound with a computed decomposition-into-elements reaction, pooled into a single population (grouping by selection provenance would be exactly the kind of between-group confound this project’s methodology is meant to catch).

Table 7: Spearman correlations, $\Delta\text{ICOHP}/\text{atom}$ (case 1, 281 reactions) against two continuous stability targets.

Target	n	ρ	p
formation_energy_per_atom	275	−0.5016	6.3×10^{-19}
energy_above_hull_eV_per_atom	279	−0.1096	0.068

(Sign: `reaction_analysis`’s products–reactants convention, opposite to `reaction_icohp.py`’s own column §6.3 — same magnitude, flipped sign.) The formation-energy result is the same relationship as §6.3’s, confirmed here on the pooled population.

Sign-based discrimination (endobondic/exobondic). Experimental viability indicator (`theoretical=False` means experimentally realized):

Table 8: Endobondic/exobondic label against experimental/theoretical status.

	endobondic	exobondic
experimental ($n = 177$)	47	130
theoretical only ($n = 98$)	17	81

Fisher’s exact test: $p = 0.10$, odds ratio = 1.72 (endobondic is $\sim 1.7\times$ more frequent among experimentally realized compounds — the expected direction, endobondic being designed as a kinetic-barrier signature — but not significant at this sample size).

Kruskal–Wallis across the three groups: $H = 2.81$, $p = 0.245$ — **not significant**, but the ordering is exactly what physics predicts: experimentally metastable compounds (known to exist despite sitting off the convex hull — exactly the category the endobondic/exobondic framework addresses) have the highest endobondic fraction; never-synthesized theoretical metastable compounds have the lowest.

Table 9: Median $\Delta\text{ICOHP}/\text{atom}$ and % endobondic by stability class ($n = 175$).

Class	n	median $\Delta\text{ICOHP}/\text{atom}$ (eV)	% endobondic
experimental metastable	59	-1.077	27.1%
stable	59	-1.589	20.3%
theoretical metastable	59	-1.659	11.9%

Reading. The 7 reference reactions reproduce almost exactly — the implementation is correct. Extending the same sign-based logic to a much larger, more heterogeneous, and generally much more comfortably stable population does not yet produce a statistically significant stable/metastable/unstable discriminant, even though every trend points the right way. This is not a contradiction: the 7 reference reactions were specifically chosen as stability edge cases ($\text{Pb}(\text{N}_3)_2$, $\text{S}_4\text{N}_2/\text{S}_4\text{N}_4$, ZnSn , Mn_2O_7) where a kinetic-barrier explanation is specifically needed; most of this project’s 281 compounds are not — they are comfortably stable or comfortably not, where the thermodynamic driving force (the formation-energy correlation above) can simply dominate the sign-based kinetic signal. The full `ViabilityLabel` machinery in `classify.py` (beyond the sign-based `BondingLabel` alone used here) needs exactly such a near-stability-boundary population — for the current dataset, decomposition into elements is strongly exothermic for almost every compound (normal for stable inorganic chemistry), which would trivially classify nearly everything `STABLE_ON_HULL` and add no information beyond what `energy_above_hull` already says directly.

7 Failures Found and Fixed

Per the instruction ("every job failure must be logged with its probable cause"), 5 of the first 178 SLURM-array-submitted jobs failed on the first pass, all diagnosed and fixed at the source (the fixes, applied to the shared SLURM/INCAR templates, carry over to the whole dataset):

- **Al_{12}W , BW , WO_2 , TcW , TiW** (all tungsten-containing): the local mirror’s `W_sv` POT-CAR is missing its `LEXCH` field entirely (confirmed by direct inspection — present in every other variant checked, including plain `W`), which VASP reads as an incompatible exchange-correlation functional and refuses to run. Fixed by replacing the `W_sv` override with plain `W` (valid PBE, verified).
- **Al_{12}W** failed again after that fix, this time with a VASP SIGSEGV — a known issue (`ulimit -s unlimited` before `vasp_std`), present in `submit_array.sh` but forgotten in `prepare_vasp_lobster.py`’s per-compound SLURM template. Fixed; recovered on retry.

Final success rate across all 394 structures computed to date: **394/394**.

8 Compute Cost

394 structures computed in total: 68 single-element references and 326 multi-element compounds (§5).

Every VASP job, then LOBSTER job, runs on the **Yargla** HPC cluster, within a single SLURM allocation of one node (`-nodes=1`) and **16 cores**: VASP under MPI parallelism (`-ntasks=16 -cpus-per-task=1, srun`), then LOBSTER under OpenMP parallelism on the same 16 cores (`OMP_NUM_THREADS=16`, single process, run sequentially after VASP within the same job). The SLURM array (`submit_array.sh`) is capped at 8 concurrent tasks.

Combined sequential total (VASP + LOBSTER, 349 structures): **55.3 h**. Given the 8-concurrent-task cap, the order of magnitude for actual elapsed time to process this volume as a

Table 10: VASP and LOBSTER compute time (n=349; timing not available for every compound).

	VASP	LOBSTER
<i>n</i>	349	348*
Mean (s)	168	404
Median (s)	58	110
Max (s)	5715 (1.6 h)	12063 (3.4 h)
Sequential total	16.3 h	39.0 h

* 1 of 349 structures had no usable LOBSTER step (trivial-cell reference element).

single batch would be ~ 6.9 h — a rough estimate (dividing by 8, ignoring queue time) given for context.

9 Current Limits and Next Steps

- **classify() coverage:** 211/394 structures (54%) fall outside the ionic/covalent/metallic categories, mostly alkali/alkaline-earth $\times$ {N, P, S} bonds that `IONIC_ANIONS` does not recognize (§5) — purely informative here, but a real limitation for any mission that would want to stratify on it.
- **No true dynamical "unstable" class:** `theo_metastable` is a proxy (never synthesized), not a phonon-calculation result.
- **Per-subgroup sample size:** remains this project's structural limit at every new stratification (`bond_type`, `is_metal`) — see §6.2 for a concrete example where an $n < 15$ subgroup did not replicate once the sample grew.
- **Why not SISSO yet:** reaction ICOHP (§6.3) is now the strongest correlate and the first whose signal is not fully explained away by between-group clustering at every level tested — the best argument yet for a stratified feature search, still not attempted.

10 Conclusion

Reitz & Dronskowski's endobondic/exobondic methodology (§6.4) reproduces faithfully across the 7 independently known reference reactions (Lin's CCC 0.999998) and applies to this report's full dataset (281 decomposition-into-elements reactions). On that population, sign-based Δ ICOHP discrimination points the expected way (endobondic more frequent among experimental compounds, and among metastable rather than stable or never-synthesized compounds) but does not reach statistical significance at this scale (§6.4). Reaction ICOHP otherwise remains the dataset's strongest and most robust continuous correlate against formation energy ($\rho = 0.502$, §6.3).

Two concrete directions follow. First, deliberately extending to compounds near the stability boundary, where a kinetic-barrier explanation is specifically needed, rather than letting the dataset grow incidentally from whatever other analyses require — most current compounds are comfortably stable or comfortably unstable, a regime where the thermodynamic driving force simply dominates the sign-based kinetic signal. Second, a new descriptor: a reaction Δ (ICOHP) restricted to a window near the Fermi level, modeled on the antibonding population of §6.2 (§2.4) rather than on the fully integrated ICOHP — since it is precisely the near- E_F window that carries the project's most robust stratified subgroup, a "near- E_F " version of the reaction Δ ICOHP is a natural, not-yet-attempted extension.

Source code: <https://github.com/John-Akapulco/viability>

Data: `analysis/percolation_vs_formation_energy.csv`

Detailed reports: `analysis/REPORT_*.md`

A Appendix: Percolation_viability

This appendix collects everything related to the percolation weight and its direct descendants (network dimensionality, periodic min-cut — missions #1 and #3): this was the central subject of the original campaign 2, unmodified below from its first drafting, but it is no longer this project's organizing question (§6.4). The corresponding source code has been moved to the repository's `Percolation_viability/` directory (`percolation_path.py`, `network_dimensionality.py`, `periodic_mincut.py`, and their tests `tests/test_percolation_path.py`, `tests/test_network_dimensionality.py`, `tests/test_periodic_mincut.py`).

A.1 Original objective (mission #1)

The very first report (6 toy compounds) established that the percolation descriptor computed by `percolation_path.py` diverges sharply from classic ICOHP aggregates (sum, mean, min, max), but without a sample large enough to statistically test whether that difference is *useful*: does the percolation descriptor carry predictive information about thermodynamic stability (`energy_above_hull`) that the classic aggregates don't already carry? Campaign 2 built a 186-compound dataset (180 new + the 6 pilot compounds) split into three families (`exp_stable`, `exp_metastable`, `theo_metastable`, §5) to settle that question.

A.2 Original workflow diagram

A.3 Campaign 2 dataset (186 compounds)

Family	n	E_{hull} range (eV/atom)
exp_stable	63	0.0000 (by construction)
exp_metastable	63	0.0005 – 0.0907
theo_metastable	60	0.0013 – 0.1991

Bond type (<code>classify()</code>)	n
metallic	88
covalent	23
ionic	9
unclassified	66

35% of compounds (66/186) fall outside `classify()`'s three categories — mostly transition-metal pnictides/chalcogenides and hydrogen-containing compounds. (Historical snapshot of campaign 2 alone; the up-to-date table across the current 349 structures is in §5.)

A.4 Results (with the percolation weight)

Group	Metric	n	ρ	p
all	percolation weight (raw)	186	0.064	0.383
all	percolation weight (normalized)	186	0.071	0.339
metallic	percolation weight (raw)	88	0.191	0.075
metallic	percolation weight (normalized)	88	0.222	0.038
ionic*	percolation weight (raw)	9	−0.402	0.284
covalent	percolation weight (raw)	23	0.165	0.453
all	ICOHP sum	186	0.032	0.670
all	ICOHP min	186	0.093	0.209
metallic	ICOHP sum	88	0.223	0.037
metallic	ICOHP min	88	0.198	0.065

* $n < 15$: do not over-interpret.

In the one subgroup where any result reaches nominal significance (metallic, $n = 88$), the normalized percolation weight ($\rho = 0.222$, $p = 0.038$) and the ICOHP sum ($\rho = 0.223$, $p = 0.037$) are statistically indistinguishable in strength. **The percolation descriptor does not demonstrate additional predictive power over the classic aggregates on this dataset.**

Reference logistic regression. Stable (on-hull) vs. metastable, features: normalized percolation weight, mean ICOHP, bond-type dummies ($n = 120$ after dropping unclassified compounds).

AUC (5-fold cross-validation)	0.496 ± 0.141
per-fold AUC	0.556, 0.430, 0.252, 0.637, 0.607

AUC ≈ 0.5 : chance level. The wide spread across folds (0.25–0.64) is itself informative: it indicates the absence of a stable, learnable signal at this sample size, not merely a "weak but real" one.

A.5 Mission #3: network dimensionality and periodic min-cut

Two new descriptors, `percolation_path.py` left unchanged: `network_dimensionality.py` (0D–3D classification via a relative bond-strength threshold + breadth-first search) and `periodic_mincut.py` (minimum cut via `networkx` max-flow, separability rather than traversability). Headline: the normalized min-cut is the **first descriptor in the project to reach a significant global correlation** ($\rho = 0.285$, $p = 1.0 \times 10^{-4}$, $n = 186$), likely driven in part by between-bond-type clustering; dimensionality alone does not separate `formation_energy_per_atom` (Kruskal–Wallis $p = 0.19$).

Why did the min-cut correlation collapse? Mission #3's headline, $\rho = 0.285$ at $n = 186$, collapsed to $\rho = 0.089$, $p = 0.098$ (not significant) at $n = 349$. **This is not a refutation of the original result** — isolated, the original 186 compounds still give $\rho = 0.2845$, $p = 8.3 \times 10^{-5}$, essentially identical to the mission-#3 number. The collapse is a dilution artifact from pooling populations added for unrelated reasons:

- 65 of the 74 extension-batch-1–3 compounds are single-element reference structures (added for mission #5's elemental references), sitting at `formation_energy_per_atom` ≈ 0 by construction with widely-scattered min-cut values — mechanically dilutes a rank correlation regardless of any true relationship. Excluding them recovers $\rho = 0.2157$ ($n = 193$).
- `extension4` is not one population but two, with *opposite-sign* correlations: the experimental half is flat ($\rho = 0.06$, not significant, $n = 50$); the deliberately far-above-hull theoretical half shows a *significant* correlation of the *opposite* sign ($\rho = -0.40$, $p = 0.011$, $n = 39$) — a higher min-cut there is associated with a *more* negative (more stable) formation energy, the reverse of the original population's trend.

This opposite sign is itself resolved (August-16 follow-up, four independent checks on the 39 `theo_far_hull` compounds, `analysis/investigate_theo_far_hull_signflip.py`): neither a cell-size/symmetry selection artifact (survives controlling for `n_sites+sg_number`, $\rho = -0.39$) nor a real physical effect of far-from-hull structures, but a **between-anion-chemistry confound** — F-containing systems (high min-cut, strongly negative formation energy) and azide N_3 -containing systems (near-zero min-cut, near-zero/positive formation energy) pull the pooled correlation in opposite directions. Controlling for anion identity (dummy regression, $n = 39$) or comparing the experimental/theoretical pair within the exact same chemical system ($n = 37$ pairs) both independently collapse the correlation to $\rho \approx -0.07$, not significant — the same between-group clustering failure mode this project has now hit three times (min-cut/`bond_type`, antibonding/`is_metal`, and now min-cut/`anion`).

Recommendation: any future min-cut-vs-formation-energy number (or, by the same logic, any other descriptor's) should be conditioned on `family`/selection-provenance, the same way this project already conditions on `bond_type`/`is_metal`.

A.6 Limits specific to the percolation weight

- **Primitive vs. conventional cell:** not reprocessed on the 186-compound dataset. Most likely explanation for the weak observed correlations — the strongest bond can sit entirely inside the primitive cell and contribute to no non-contractile cycle at all, biasing the measured "weakest link." Tested on the 6 pilot compounds (mission #2): the choice changes the percolation weight substantially (3x-55x) but in the *opposite* direction from the hypothesis (the weight gets *smaller* with a larger cell); not extended to the full dataset based on this result.
- **Chance-level reference logistic regression** ($AUC \approx 0.5$) with percolation weight as a feature.
- **Why not SISSO:** a single candidate descriptor (the percolation weight, in two algebraically related variants), compared against aggregates that are themselves functions of the same underlying ICOHP values — no meaningful combinatorial search space at this stage.

A.7 Conclusion of the original campaign

The 186-compound dataset was built, computed (VASP+LOBSTER), and analyzed end to end. The headline result is a *negative* but quantified and honest one: at this sample size, the percolation descriptor shows no significant correlation with thermodynamic stability, and demonstrates no advantage over classic ICOHP aggregates. This result, together with the min-cut result (mission #3), motivated the project’s reframing around $\Delta(\text{ICOHP})$ documented in §6.4.

A.8 Compound List (percolation weight)

Campaign 2’s 186 compounds, grouped by category (family), with their Materials Project identifier, PBE thermodynamic hull distance (`energy_above_hull`), and the minimum ICOHP percolation weight (`icohp_percolation_weight_min`). Auto-generated from `analysis/percolation_vs_hull.csv` by `report/gen_appendix.py`.

Table S1: Complete list of the 186 compounds, grouped by category, with their Materials Project identifier, PBE hull distance, and minimum ICOHP percolation weight.

B VASP Calculation Parameters

Fixed INCAR parameters, identical across the whole dataset (static, LOBSTER-compatible run) — only NBANDS (appendix D) and the k-point grid vary by compound.

Parameter	Value	Description
PREC	Accurate	Overall precision (charge grid, projectors)
ENCUT	600.0	Plane-wave cutoff energy (eV)
EDIFF	1e-06	Electronic convergence criterion (eV)
IBRION	-1	Ionic dynamics type (-1 = static, no relaxation)
NSW	0	Number of ionic steps (0 = static run on the MP structure)
ISMear	0	Smearing type (0 = Gaussian)
SIGMA	0.05	Smearing width (eV)
LASPH	True	Non-spherical corrections to the PAW potential
ISYM	-1	Symmetry (-1 = disabled, required by LOBSTER)
LWAVE	True	Write WAVECAR (required by LOBSTER)
LCHARG	True	Write CHGCAR
NPAR	4	Band-level parallelization
KPAR	2	K-point-level parallelization

C PAW-PBE Potentials

One PAW-PBE potential per element present in the dataset (pymatgen’s `MPRelaxSet` library — the same one Materials Project used to relax the input structures), with one documented exception for tungsten (§7): the recommended `W_pv` variant is absent from the local mirror, and `W_sv` turned out to be corrupted (missing `LEXCH` field) — plain `W` is used instead, verified valid.

Table S2: PAW-PBE potentials used, one per element present in the dataset (pymatgen’s `MPRelaxSet` library, with one documented exception: `W` substituted for `W_pv`/`W_sv`, see §7).

Element	PAW-PBE potential

D k-point Grid and NBANDS per Compound

k-point grid auto-generated by `pymatgen.io.vasp.Kpoints.automatic_density_by_vol` (density `kppv1=100`, Γ -centered or Monkhorst–Pack mesh depending on cell symmetry) and `NBANDS`, derived per compound from the number of local orbitals in the LOBSTER basis (`Lobsterin.write_INCAR`) — a strictly sufficient value for the local-basis projection, not a fixed guess.

Table S3: k-point grid (pymatgen automatic density, `kppvol=100`) and number of bands (derived from the LOBSTER basis) per compound.

E Elements and Allotropes

Every single-element structure with no matched polymorph in the dataset: the elemental references (**ELEMENT_REFERENCE**) used to decompose multi-element compounds. An experimental compound’s formula is marked with a superscript star (black if it is the stable phase, red if it is a metastable polymorph/allotrope); unmarked formulas are theoretical. Auto-generated by `report/gen_appendix_extension.py`.

Table S4: Elements and allotropes with no matched polymorph in the **extension** campaign: references used to decompose multi-element compounds. Allotropes with one or more other allotropes computed in this dataset (e.g. carbon) are grouped in Table S5 instead. Black * = stable experimental reference (thermodynamic phase); red * = metastable experimental reference; unmarked = theoretical. No Δ ICOHP column: an element is not itself a decomposition reaction.

F Polymorphs and Allotropes

Elements and compounds with several entries sharing a formula in the dataset, grouped here rather than scattered across the elements/compounds tables (see the table caption for detail).

Table S5: Elements (allotropes) and compounds (polymorphs) with **several entries sharing a formula** in the **extension** campaign (54 groups, 130 entries) — grouped here rather than scattered across the elements/compounds tables, since the natural comparison for a polymorph group is polymorph-to-polymorph, not the decomposition-to-elements reaction (hence no ΔICOHP column). A rule separates each group; within a group, sorted by increasing E_{hull} . Black * = stable experimental; red * = metastable experimental; unmarked = theoretical.

G Target Compounds

Every multi-element target compound with no matched polymorph in the dataset, with ΔICOHP per atom and its endobondic/exobondic label where a case-1 decomposition reaction could be computed. Auto-generated from `analysis/reaction_icohp_case1.csv` and `analysis/reaction_analysis_ca` by `report/gen_appendix_extension.py`.

Table S6: Target compounds with no matched polymorph in the **extension** campaign. Formulas with several entries in this dataset are grouped in Table S5 instead. Black * = stable experimental compound (thermodynamic phase); red * = metastable experimental compound; unmarked = theoretical. ΔICOHP per atom, products – reactants convention (`reaction_analysis`); “–” where no case-1 reaction could be computed (missing elemental reference).

Formula	mp-id / COD	Space group	E_{hull} (eV/at)	ΔICOHP /at. (eV)	Label

H Endobondic Reactions

The subset of case-1 decomposition reactions ($A_a B_b \rightarrow a A + b B$, standard-state elemental references, balanced by `reaction_icohp.py`) labeled **endobondic** ($\Delta\text{ICOHP} \geq 0$, products – reactants convention — note this is the sign *opposite* `reaction_icohp.py`’s own `delta_icohp_per_atom` column reported elsewhere in this project; see `delta.py`’s docstring).

Table S7: Decomposition-into-elements (case 1) reactions labeled **endobondic** ($\Delta\text{ICOHP} \geq 0$, products – reactants) among the 208 compounds of the **extension** campaign. Black * = stable experimental starting compound; red * = metastable experimental.

I Exobondic Reactions

The complementary **exobondic** subset ($\Delta\text{ICOHP} < 0$), same convention and provenance as Appendix H.

Table S8: Decomposition-into-elements (case 1) reactions labeled **exobondic** ($\Delta\text{ICOHP} < 0$, products – reactants) among the 208 compounds of the **extension** campaign. Black * = stable experimental starting compound; red * = metastable experimental.

J ICOHP and ICOBI Antibonding Descriptors

J.1 Implementation

The ICOHP antibonding-population-near-frontier descriptor (§6.2, `cohpy_extraction.py`) is extended here to ICOBI: same one-sided window ($E_{\text{ref}} - \Delta E$, E_{ref}], same E_{ref} (Fermi level for metals,

VBM for gapped compounds — logic entirely independent of which curve is integrated), read this time from `COBICAR.lobster/ICOBILIST.lobster` instead of `COHPCAR.lobster/ICOHPLIST.lobster` (`pymatgen.io.lobster.outputs.Cohpcar(are_cobis=True)`).

Critical point, empirically verified, not assumed: ICOBI does **not** share ICOHP's sign convention. Whereas "negative ICOHP = bonding" (§2.4), ICOBI follows the opposite convention, "positive ICOBI = bonding" (like COOP, not like COHP). Verified two ways on real data: (1) exact cross-check against `ICOBILIST.lobster` (max deviation 0.0 across 66 bond labels, `tests/test_cohp_extraction.py`) — `pymatgen` does not silently renormalize the sign when switching from COHP to COBI parsing; (2) on `extension_SiO2_anchor`'s strongest Si–O bond (ICOHP = -5.599 , ICOBI = $+0.513$), the deep bonding region (-10 to -3 eV, far from any frontier effects) gives a mean COHP(E) of -0.338 but a mean COBI(E) of $+0.041$ — opposite signs in the same physically bonding-dominated region. ICOBI's antibonding part is therefore its *negative* part, not its positive part – the clip direction (`integrate_icobi_antibonding_in_window()`) is deliberately the mirror image of the ICOHP version, not a copy.

Computed across the 394 compounds with a `COBICAR.lobster` file (`analysis/compute_icobi_antibonding.392` with `is_metal` available).

J.2 Correlation with formation energy

Table S9: Spearman correlations (normalized, $\Delta E = 1.0$ eV) against `formation_energy_per_atom` — ICOHP (n=394) and ICOBI (n=392) antibonding, same population.

Group	n (ICOHP)	ρ (ICOHP)	n (ICOBI)	ρ (ICOBI)
all	391	-0.2473^{***}	385	$+0.2518^{***}$
covalent	40	-0.4781^{**}	38	-0.1755
ionic	53	-0.1842	51	$+0.1289$
metallic	88	-0.1864	86	$+0.0011$
<code>is_metal=False</code>	166	-0.2621^{***}	162	$+0.0661$
<code>is_metal=True</code>	225	-0.0154	223	$+0.1263$

** $p < 0.01$; *** $p < 0.001$; no star = not significant. Full detail (raw + normalized, all three ΔE):

`analysis/stats_summary_antibonding_joint.json`.

The two descriptors behave differently. ICOBI antibonding's global sign is the *opposite* of ICOHP antibonding's ($+0.25$ vs. -0.25) — for ICOHP, more occupied antibonding character

near E_F is associated with *more* stable formation (already noted as counterintuitive in §6.2); for ICOBI, the relationship runs the naively expected way (more antibonding $\Rightarrow$ less stable). But **no ICOBI subgroup survives stratification** (covalent, ionic, metallic, `is_metal`: $p > 0.05$ throughout) — unlike ICOHP, whose covalent subgroup ($n = 40$, $\rho = -0.478$) remains the project’s most robust stratified result. ICOBI’s global correlation is therefore, like reaction ICOHP’s (§6.3), likely a between-bond-type clustering effect rather than a robust relationship within a homogeneous group.

J.3 Δ (antibonding) of the decomposition-into-elements reaction

For a case-1 reaction (compound $\rightarrow$ elements), Δ (antibonding) is **not** computed by `reaction_analysis/delta.py` (which combines *extensive* per-formula-unit ICOHP/ICOBI sums with integer coefficients): the antibonding population near the frontier is built from LOBSTER’s own "average" trace, an *intensive* quantity (averaged over all bonds, not summed) with no natural extensive decomposition. Convention chosen here, documented as an explicit methodological choice rather than a silent reuse: $\Delta =$ (atomic-fraction-weighted average of the elements’ own antibonding descriptors) – (the compound’s own antibonding descriptor), still in products – reactants convention. Computed for 320 case-1 reactions (`analysis/compute_delta_antibonding_case1.py`).

Table S10: Spearman correlations, Δ (antibonding) of the decomposition reaction (case 1, $n = 316$ –320).

Descriptor	Target	n	ρ
Δ (ICOHP antibonding)	<code>formation_energy_per_atom</code>	316	–0.6439***
Δ (ICOBI antibonding)	<code>formation_energy_per_atom</code>	316	–0.4457***
Δ (ICOHP antibonding)	<code>energy_above_hull</code>	320	–0.1868***
Δ (ICOBI antibonding)	<code>energy_above_hull</code>	320	–0.1524**

** $p < 0.01$; *** $p < 0.001$.

Δ (ICOHP antibonding) is, at this stage, the strongest continuous correlation in the whole project ($\rho = -0.644$, stronger than reaction ICOHP in §6.3, $\rho = 0.502$). Notable: unlike the raw values (opposite signs, above), **both Δ s run the same direction** (both negative) — the delta construction appears to align the two descriptors on a consistent reading, where their raw values do not. The two Δ s are themselves correlated with each other ($\rho = 0.532$, $p < 0.001$, $n = 320$): related but not redundant.

J.4 Stratification by bond type

Table S11: Spearman correlations, Δ (antibonding) against `formation_energy_per_atom`, by subgroup (case 1, $n = 316$).

Subgroup	n	ρ (Δ ICOHP)	n	ρ (Δ ICOBI)
all	316	–0.6439***	316	–0.4457***
covalent	29	–0.5798***	29	–0.2044
ionic	51	–0.4205**	51	+0.0608
metallic	86	–0.4858***	86	–0.4872***
<code>is_metal=False</code>	145	–0.6210***	145	–0.3248***
<code>is_metal=True</code>	171	–0.5490***	171	–0.4653***

** $p < 0.01$; *** $p < 0.001$; no star = not significant.

$\Delta(\text{ICOHP antibonding})$ is, to date, the first descriptor in the whole project whose global correlation survives *every* stratification tested — covalent, ionic, metallic, `is_metal` on both sides, all significant at $p < 0.01$ or better. No other descriptor in this report manages that: the raw antibonding population (§6.2) keeps only its covalent subgroup, reaction ICOHP (§6.3) loses every `bond_type` stratum and survives only on `is_metal`. $\Delta(\text{ICOBI antibonding})$ is more mixed: survives on metallic and both `is_metal` sides but not on covalent ($p = 0.29$) or ionic ($p = 0.67$). This remains a newly chosen construction (previous subsection) — its magnitude will need to reproduce on an independent dataset before being treated as a fully established result, but surviving full stratification makes it, as it stands, the project’s most robust result.
